-
-

Abstract—Evolutionary algorithms can outperform conventional placement algorithms such as simulated annealing, analytical placement as well as manual placement on metrics such as runtime, wirelength, pipelining cost, and clock frequency when mapping FPGA hard block intensive designs such as systolic arrays on Xilinx UltraScale+ FPGAs. For certain hard-block intensive, systolic array accelerator designs, the commercial-grade Xilinx Vivado CAD tool is unable to provide a legal routing solution without tedious manual placement constraints. Instead, we formulate an automatic FPGA placement algorithm for these hard blocks as a multi-objective optimization problem that targets wirelength squared and maximum bounding box size metrics. We build an end-to-end placement and routing flow called RapidLayout using the Xilinx RapidWright framework. RapidLayout runs 5–6 \times faster than Vivado with manual constraints, and eliminates the weeks long effort to manually generate placement constraints for the hard blocks. We also perform automated post-placement pipelining of the long wires inside each convolution block to target 650 MHz URAM-limited operation. RapidLayout outperforms (1) the simulated annealer in VPR by 33% in runtime, 3.7 \times in wirelength, and 3 \times in bounding box size, while also (2) beating the analytical placer UTPlaceF by 9.2 \times in runtime, 1.7–1.9 \times in wirelength, and 2–3 \times in bounding box size. We employ transfer learning from a base FPGA device to speed-up placement optimization for similar FPGA devices in the UltraScale+ family by 7–12 \times than learning the placements from scratch.

I. INTRODUCTION

Modern high-end FPGAs provide high compute density with a heterogeneous mixture of millions of classic lookup tables and programmable routing network along with tens of thousands of DSP and RAM hard blocks. These hard blocks offer ASIC-like density and performance for signal processing functions, and on-chip SRAM access. For example, Xilinx UltraScale+ VU11P is equipped with 960 UltraRAM blocks, 4032 Block RAM slices, and 9216 DSP48 blocks capable of operating at 650–891 MHz frequencies which are typically unheard of with LUT-only designs. Furthermore, these hard blocks provide specialized nearest-neighbour interconnect for high-bandwidth, low-latency *cascade* data movement. These features make it particular attractive for building systolic neural network accelerators such as CLP [28], [29], Cascades [27], and Xilinx SuperTile [34], [35].

Exploiting the full capacity of FPGA resources including hard blocks at high clock frequency is challenging. The

CLP designs presented in [28], [29] only operate at 100–170 MHz on Virtex-7 FPGAs but leave DSPs unused. The Xilinx SuperTile [34], [35] designs run at 720 MHz, but leaves half the DSPs unused, and also wastes URAM bandwidth by limiting access. The chip-spanning 650 MHz 1920 \times 9 systolic array design for the VU11P FPGA [27] requires 95% or more of the hard block resources but fails routing in commercial-grade Xilinx Vivado run with high effort due to congestion. Manual placement constraints are necessary to enable successful bitstream generation but this requires weeks of painful trial-and-error effort and visual cues in the Vivado floorplanner for correct setup. This effort is needed largely due to irregularity and asymmetry of the columnar DSP and RAM fabric and the complex cascade constraints that must be obeyed for the systolic data movement architecture. Once the constraints are configured, Vivado still needs 5–6 hours of compilation time, making design iteration long and inefficient. Furthermore, to ensure high-frequency operation, it becomes necessary to pipeline long wires in the design. Since timing analysis must be done post-implementation, we end up either suffering the long CAD iteration cycles, or overprovisioning unnecessary pipelining registers to avoid the long design times.

Given this state of affairs with the existing tools, we develop RapidLayout: an alternative, automated, fast placement approach for hard block designs. It is important that such a toolflow address the shortcomings of the manual approach by (1) discovering correct placements quickly without the manual trial-and-error loop through slow Vivado invocations, (2) encoding the complex placement restrictions of the data movement within the systolic architecture in the automated algorithm, (3) providing fast wirelength estimation to permit rapid objective function evaluation of candidate solutions, and (4) exploiting design symmetry and overcoming irregularity of the columnar FPGA hard block architecture. Given this wish list, we used the Xilinx RapidWright framework for our tool.

At its core, the toolflow is organized around the design of a novel evolutionary algorithm formulation for hard block placement on the FPGA through multi-objective optimization of wirelength squared and bounding box metrics. Given the rapid progress in machine learning tools, there is an opportunity to revisit conventional CAD algorithms [5], including the one in this paper, and attack them with this new toolbox.

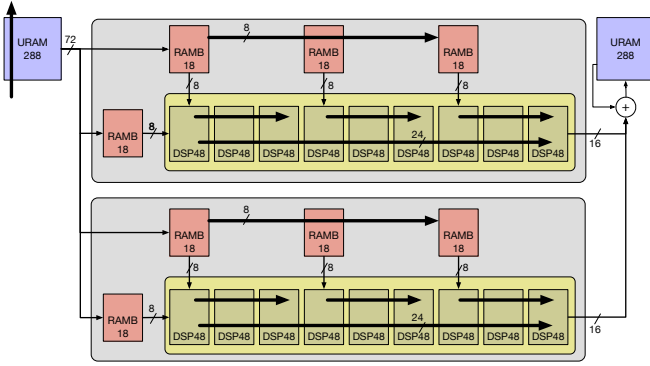

Fig. 1. Convolutional Building Block for FPGA-Optimized Systolic Array in [27]. Cascade URAM, BRAM, and DSP links are highlighted in bold.

The key contributions of this work are listed as follows:

- We formulate a novel FPGA placement problem for tens of thousands of hard blocks as a multi-objective optimization using evolutionary techniques.
- We quantify QoR metrics including runtime, wirelength, bounding box size, clock frequency, and pipelining cost for the evolutionary placement algorithms NSGA-II and CMA-ES. We compare these metrics against conventional Simulated Annealing (SA), Genetic Algorithm (GA), Versatile-Place-and-Route (VPR) [22], and the state-of-art analytical placer UTPlaceF [19].
- We build an end-to-end RapidLayout placement-and-routing toolflow using the open-source Xilinx RapidWright framework.
- We develop the transfer learning process for hard block placement to accelerate placement optimization through migrating existing placement from base devices to similar devices in the UltraScale+ family (VU3P–VU13P).

II. BACKGROUND

We first discuss the hard block intensive systolic array accelerator optimized for the Xilinx UltraScale+ FPGAs. Next, we discuss the Xilinx RapidWright framework for programming FPGAs through a non-RTL design flow. Then, we describe previous research on FPGA placement algorithms. Finally, we review the classic NSGA-II algorithm and the state-of-art CMA-ES algorithm and compare them with previous efforts on evolutionary placement.

A. FPGA-optimized Systolic Array Accelerator

Systolic arrays [14], [16] are tailor-made for convolution and matrix operations needed for neural network acceleration. They are constructed to support extensive data reuse through nearest-neighbor wiring between a simple 2D array of multiply-accumulate blocks. They are particularly amenable to implementation on the Xilinx UltraScale+ architecture with cascade nearest-neighbor connections between DSP, BRAM, an URAM hard blocks. We utilize the systolic convolutional neural network accelerator presented in [27] and illustrated in Figure 1. The key repeating computational block is a convolution engine optimized for the commonly-used 3×3 convolution operation. This is implemented across a chain of

9 DSP48 blocks by cascading the accumulators. Furthermore, row reuse is supported by cascading three BRAMs to supply data to a set of three DSP48s each. Finally, the URAMs are cascaded to exploit all-to-all reuse between the input and output channels in one neural network layer. Overall, when replicated to span the entire FPGA, this architecture uses 95–100% of the DSP, BRAM, and URAM resources of the high-end UltraScale+ VU37P device. When mapped directly using Vivado without any placement constraints, the router runs out of wiring capacity to fit the connections between these blocks. Since the convolution block is replicated multiple times to generate the complete accelerator, it may appear that placement should be straightforward. However, due to irregular interleaving of the hard block columns, and the non-uniform distribution of resources, the placement required to fit the design is quite tedious and takes weeks of effort.

B. RapidWright

In this paper, we develop our tool based on the Xilinx RapidWright [17] open-source FPGA framework. It aims to improve FPGA designer productivity and design QoR (quality of result) by composing large FPGA designs through pre-implemented and modular methodology. RapidWright provides high-level Java API access to low-level Xilinx device resources. It supports design generation, placement, routing, and allows design checkpoint (DCP) integration for seamless inter-operability with Xilinx Vivado CAD tool to support custom flows. RapidWright provides access to both the logical and physical netlist of designs, and allows netlist editing facility that enables non-RTL design generation opportunities. It also provides access to device geometry information that enables wirelength calculations crucial for tools that aim to optimize timing.

C. FPGA Placement

FPGA placement maps a clustered logical circuit to an array of fixed physical components to optimize routing area, critical path, power efficiency, and other metrics. FPGA placement algorithms can be broadly classified into four categories: (1) classic min-cut partitioning [23], [24], [31], (2) popular simulated-annealing-based methods [2], [3], [15], [22], (3) analytical placement currently used in FPGA CAD tools [1], [8], [9], [19], and (4) esoteric evolutionary approaches [4], [13], [32]. Min-cut algorithm worked well on small FPGA capacities by iteratively partitioning the circuit to spread the cells across the device. Simulated Annealing was the popular choice for placement until recently and operates by randomly swapping clusters in an iterative, temperature-controlled fashion resulting in progressively higher quality results. Analytical placers are currently industry standard as they solve the placement problem using linear algebraic approach that delivers higher quality solutions with less time than annealing. For example, Vivado uses an analytical placement to optimize timing, congestion and wirelength [8].

D. Evolutionary Algorithms

There have been several attempts of deploying evolutionary algorithms for FPGA placement with limited success. The earliest one by Venkatraman and Patnaik [32] encodes each two-dimensional block location in a gene, and evaluates the population with a fitness function for critical path and area-efficiency. More recently, P. Jamieson [11], [12] points out GAs for FPGA placement are inferior to annealing mainly due to the weakness of crossover operator, and proposed a clustering technique called supergenes [13] to improve its performance.

In this paper, we design a novel combinational gene representation for FPGA hard block placement, and explore two evolutionary algorithms:

1. **NSGA-II**: Non-Dominated Sorting Genetic Algorithm (NSGA-II [6]) is a two decade-old multi-objective evolutionary algorithm that has grown in popularity today for Deep Reinforcement Learning [18] and Neural Architecture Search [20] applications. NSGA-II addresses multi-objective selection with non-dominated filtering and crowd distance sorting, which allow the algorithm effectively explore the solution space and preserve good candidates.
2. **CMA-ES**: Covariance Matrix Adaptation Evolutionary Strategy (CMA-ES) is a continuous domain optimization algorithm for non-linear, ill-conditioned, black-box problems [10]. CMA-ES models candidate solutions as samplings of a n -dimensional Gaussian variable with mean μ and covariance matrix C_σ . At each evolutionary iteration, the population is generated by sampling from \mathbb{R}^n with updated mean and covariance matrix. Here, cross-over and mutation become adding Gaussian noise to the samplings, which overcomes the weakness of GA's crossover operator. We use the high-dimensional variant proposed in [26] for fast operation in our placement challenge.

III. RAPIDLAYOUT

The challenge for mapping FPGA-optimized systolic arrays to the Xilinx UltraScale+ device is the placement of hard blocks to their non-uniform, irregular, columnar locations on the fabric while obeying the cascade data movement constraints. We first present our problem formulation, and then discuss how to embed it into the evolutionary algorithms.

A. Problem Formulation

To tackle the placement challenge, we formulate the coarse-grained placement of RAMs and DSP blocks as a constrained multi-objective optimization problem. The placement for rest of the logic *i.e.* lookup tables (LUTs) and flip-flops (FFs) is left to Vivado's placer. The multi-objective optimization goal is formalized as follows.

$$\min \sum_{i,j} ((\Delta x_{i,j} + \Delta y_{i,j}) \cdot w_{i,j})^2 \quad (1)$$

$$\min(\max_k BBoxSize(C_k)) \quad (2)$$

subject to:

$$0 \leq x_i, y_i < XMAX, YMAX \quad (3)$$

$$x_i, y_i \neq x_j, y_j \quad (4)$$

if i is cascaded after j in the same column: $x_i = x_j$

$$y_i = \begin{cases} y_j + 1 & i, j \in \{DSP, URAM\} \\ y_j + 2 & i, j \in \{RAMB\} \end{cases} \quad (5)$$

In the equations above:

- $i \in \{DSP, RAM, URAM\}$ denotes physical hard block on which a logic block is mapped.
- C_k denotes a convolution unit k that contains 2 URAMs, 18 DSPs, and 8 BRAMs.
- $\Delta x_{i,j} + \Delta y_{i,j}$ is Manhattan distance between the two physical hard blocks i and j .
- $w_{i,j}$ is the weight for wirelength estimation, here we are using the number of nets (connections) between hard block i and j .
- $BBoxSize()$ is the largest bounding box rectangle containing the hard block resources of a convolution unit C_k .
- x_i and y_i denotes the RPM absolute grid co-ordinates of hard block i that are needed to compute wirelength and bounding box sizes [36].

Understanding the Objective Function: We approximate routing congestion performance with squared wirelength (Equation 1) and critical path length with maximum bounding box size (Equation 2). These twin objectives try to reduce pipelining requirements while maximizing clock frequency of operation. While this seems odd optimization target for our solver, we have observed cases where chasing wirelength² alone has misled the optimizer into generating large bounding boxes for a few stray convolution blocks. In contrast, optimizing for maximum bounding box alone was observed to be extremely unstable and caused convergence problems. Hence, we choose these two objective functions to restrict the spread of programmable fabric routing resources, and reduce the length of critical path between hard blocks and associated control logic fanout.

Understanding Constraints The optimizer only needs to obey three constraints. The **region constraint** in Equation 3 restrict the set of legal locations for the hard blocks to a particular repeatable rectangular region of size $XMAX \times YMAX$ on the FPGA. The **exclusivity constraint** in Equation 4 forces the optimizer to prevent multiple hard block should be assigned to the same physical location. The **cascade constraint** in Equation 5 is the “uphill” connectivity restriction imposed due to the nature of the Xilinx UltraScale+ DSP, BRAM, and URAM cascades. For DSPs and URAMs, it is sufficient to place connected blocks next to each other. For BRAMs, the adjacent block of the same type resides at one block away from the current location. This is because RAMB180 and RAMB181, which are both RAMB18 blocks, are interleaved in the same column.

Fig. 2. Our three-tier genotype design for hard block placement. (a) Distribution defines the amount of hard blocks to be placed in each column. (b) Location encodes the relative position of the corresponding hard blocks in its column. (c) Mapping defines the connectivity of hard blocks, i.e., which hard blocks are mapped to one convolution unit. The selected physical hard-block groups are numbered, which corresponds to the mapping genotype.

1) *Genotype Design for Evolutionary Algorithms:* We decompose placement into three sub-problems and encode the candidate solutions with a novel composite genotype design.

1. **Distribution** Since the systolic array accelerator does not perfectly match the hard block resource capacity, we allocate hard blocks across resource columns according to the distribution genotype.
2. **Location** Once we choose the exact number of blocks to place on a given resource column, we assign each block in the column a location according to a value between $0 \rightarrow 1$.
3. **Mapping** Finally, we label selected blocks and allocate them to each convolution unit according to the mapping genotype. This is a permutation genotype that optimizes the order of elements without changing its value.

In Figure 2, we visualize the genotype design which consists of the three parts just discussed earlier. During evolution, each part of the genotype is updated and decoded independently, but are evaluated together.

2) *Solution Legalization:* The genotype is designed in real quantities to accommodate both NSGA-II and CMA-ES. Therefore, we must **legalize** the genotype into integers for use with actual FPGA placement. We need two solution legalization processes, one for distribution and the other for location. For the distribution genotype, this requires quantizing and clipping the resources to the maximum available quantity in each hard block column while ensuring all required resources have a column assigned to them. For the location genotype, each float value defines the relative position in the column for one group of cascaded hard blocks, $0 \rightarrow 1$ corresponds to the south \rightarrow north layout direction in the column. During quantization, we take care to avoid overlapping assignments.

B. RapidLayout Design Flow

We now describe the end-to-end RapidLayout design flow: the approximate runtime of each stage and its interaction with RapidWright and Vivado.

- **Netlist Replication ($\approx 1s$)** RapidLayout starts with a synthesized netlist of the convolution unit with direct instantiations of the FPGA hard blocks. The unit design is replicated into the entire logical netlist that maps to the whole Super Logic Region (SLR).
- **Evolutionary Hard Block Placement (30 s-5min)** RapidLayout uses NSGA-II or CMA-ES to generate hard block placement for the minimum repeating rectangular region. Then the rectangular layout is replicated (*copy-paste*) to produce the placement solution for the entire SLR.
- **Placement and Site Routing ($\approx 3min$)** The placement information is embedded in the DCP netlist by placing the hard blocks on the physical blocks called “sites”, followed by “site-routing” to connect intra-site pins.
- **Post-Placement Pipelining ($\approx 10s$)** After finalizing placement, we can compute the wirelength for each net in the design and determine the amount of pipelining required for high-frequency operation. This is done post-placement [7], [30], [33] to ensure the correct nets are pipelined and to the right extent. The objective of this step is to aim for 650 MHz URAM-limited operation as dictated by the architectural constraints of the systolic array [27].
- **SLR Placement and Routing ($\approx 55min$)** Once the hard blocks are placed and pipelined, we call Vivado to complete LUT/FF placement and routing for the SLR.
- **SLR Replication (1-5 min)** RapidLayout copies placement and routing of the SLR across the entire device using RapidWright APIs to complete the overall design implementation.

For the VU11P device, RapidLayout accelerates the end-to-end implementation flow by $\approx 5-6\times$ when measuring FPGA CAD runtime alone (\approx one hour vs. Vivado’s 5-6 hours). This does not include the weeks of manual tuning effort that is avoided by automatically discovering the best placement for the design.

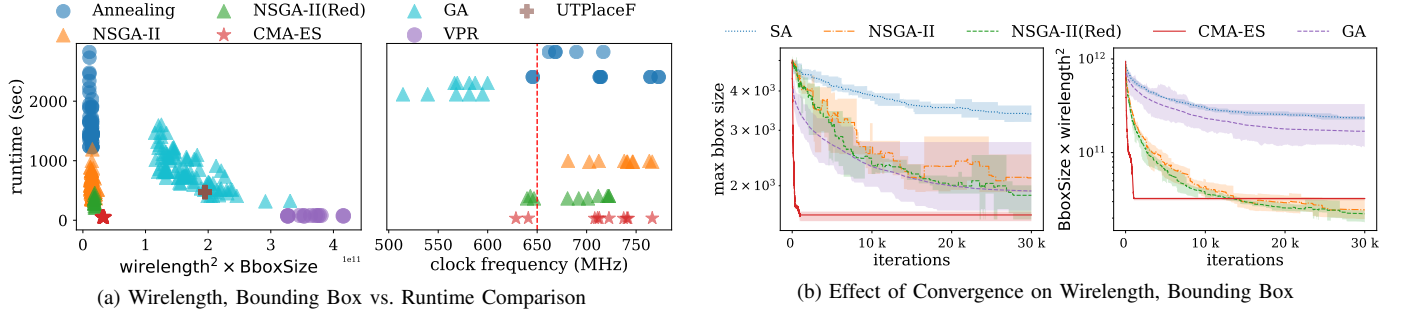

Fig. 3. Performance, Wirelength, and Bounding Box Comparison: SA, NSGA-II, NSGA-II (Red), and CMA-ES

TABLE I

RUNTIME(AVG), WIRELENGTH(AVG), MAX BBOX(AVG), PIPELINING REGISTERS(MIN), AND FREQUENCY(AVG) FOR ALL METHODS. NSGA-II SHOWS REDUCED GENOTYPE AS WELL. SPEEDUPS AND QoR IMPROVEMENTS WINS BY EVOLUTIONARY ALGORITHMS ALSO REPORTED IN **RED**→NSGA-II AND **GREEN**→CMA-ES FOR EACH COMPETITOR ALGORITHM (SA, GA, UTPLACEF, VPR, MANUAL).

Method	NSGA-II	CMA-ES	SA	GA	VPR	UTPlaceF	Manual
Runtime (secs)	586 (323)	51	1577 (2.7×, 30.8×)	850 (1.5×, 16.7×)	76 (0.13×, 1.5×)	473 (0.8×, 9.3×)	1–2 wks
Wirelength	3.5K (3.5K)	4.4K	3.1K (0.9×, 0.7×)	9.2K (2.6×, 2.1×)	8.5K (2.4×, 1.9×)	7.8K (2.2×, 1.8×)	8.1K (2.3×, 1.8×)
BBox	1183 (1543)	1606	1387 (1.2×, 0.9×)	1908 (1.6×, 1.2×)	4941 (4.1×, 3.1×)	3218 (2.7×, 2.0×)	1785 (1.5×, 1.1×)
Pipeline Reg.	256K (273K)	273K	273K (1.1×, 1×)	323K (1.3×, 1.2×)	-	-	306K (1.2×, 1.1×)
Frequency (MHz)	733 (688)	708	711 (0.97×, 1.0×)	585 (0.80×, 0.83×)	-	-	693 (0.95×, 0.98×)

IV. RESULTS

RapidLayout is implemented in Java to enable seamless integration with RapidWright Java APIs. We use the Java library Opt4J [21] with multi-threading enabled as the optimization framework for NSGA-II, SA and GA. CMA-ES is implemented with Apache Commons Math Optimization Library [25] 3.4 API. We use VPR 7.0 official release [22] and UTPlaceF TCAD version [19] binary for QoR comparison. All placed designs are routed and timed with Vivado Design Suite 2018.3. We run our experiments on an Ubuntu 16.04 LTS machine with Intel Xeon CPU and 128 GB RAM.

A. Performance and QoR Comparison

We compare the performance and QoR of evolutionary algorithms against: (1) conventional simulated annealing (SA), (2) academic placement tool VPR 7.0, (3) state-of-art analytical placer UTPlaceF, (4) single-objective genetic algorithm (GA), and (5) manual placement design. RapidWright’s default annealing-based block placer does not give feasible placement solution because it cannot discover enough placement anchors for Module Instances. We run each placement algorithm 50 times with seeded random initialization. Then, we select the top-10 results for each method to route and report clock frequency. While we include VPR and UTPlaceF in the comparisons, they do not support **cascade** constraints (Equation 5). This limits our comparison to an approximate check on solution quality and runtime and are unable to directly translate the resulting placement to the FPGA.

In Figure 3a, we plot total runtime and final optimized $\text{wirelength}^2 \times \text{maximum bounding box size}$ for the different placement algorithms along with Vivado-reported frequency results. We see some clear trends here: (1) NSGA-II is $\approx 2.7\times$ faster than SA and delivers 14.7% bounding box improvement,

but has $\approx 12.9\%$ longer wirelength. Even the average clock frequency of top-10 results is evidently higher than SA as NSGA-II’s performance is more stable. (2) CMA-ES is $\approx 30\times$ faster than SA. Although the average bounding box size ($\approx 41\%$ larger) and wirelength ($\approx 16\%$ larger) are worse than SA’s results, CMA-ES achieves a slightly higher average clock frequency at 711 MHz. (4) An alternate NSGA-II method discussed later in Section IV-B2 with a reduced search space delivers roughly 5 times shorter runtime, with only 2.8% clock frequency degradation, which is still above the URAM-limited 650 MHz maximum operating frequency.

In Figure 3b, we see the convergence rate of the different algorithms when observing bounding box sizes and the combined objective. NSGA-II clearly delivers better QoR for wirelength after 15 k iterations, while CMA-ES delivers smaller bounding box sizes within a thousand iterations. Across 50 runs, bounding box optimization shows a much more noisy behavior with the exception of CMA-ES. This makes it (1) tricky to rely solely on bounding box minimization and (2) suggests a preference for CMA-ES for containing critical paths within bounding boxes.

Finally, in Table I, we compare average metric values across the 50 runs with all methods. NSGA-II and CMA-ES deliver superior QoR and runtime against UTPlaceF and VPR, and speeds up runtime by 3–30× against annealing with a minor loss in QoR. Table I also reports the number of registers needed for 650 MHz operation. NSGA-II delivers this with 17k ($\approx 6\%$) less registers against annealing and 50k ($\approx 16\%$) less registers against manual placement.

B. Parameter Tuning for Annealing and NSGA-II

In this section, we discuss cooling schedule selection for annealing and optimizations to NSGA-II to explore quality, runtime tradeoffs.

1) *Parameter Tuning for SA*: Cooling schedule determines the final placement quality, but it is highly problem specific. We plot the cooling schedule tuning process in Figure 4, and choose hyperbolic cooling schedule for placement experiments to achieve the best result quality.

Fig. 4. SA Parameter Tuning. Each type of cooling schedule is experimented with 10 sets of parameter combination. We select hyperbolic cooling schedule with the best parameter combination for annealing placement experiments

2) *NSGA-II Reduced Genotype*: As per the genotype design, distribution and location genotypes take up a large portion of the composite genotype, and they demand special legalization steps. However, for high-utilization designs, distribution and location are less influential since resources are nearly fully utilized. Therefore, we reduce the genotype to mapping only for NSGA-II, and uniformly distribute and stack the hard blocks from bottom to top. As a consequence of this trade-off, we observe a 44.8% runtime improvement but a 30.4% larger bounding box size. In the convergence plot of Figure 3b, we discover that reduced genotype does not save iteration needed and the bulk of the runtime improvements comes from reduced genotype decoding and legalization work.

C. Pipelining

Finally, we explore the effect of pipelining stages on different placement algorithms. At each pipelining depth, multiple placements from each algorithm is routed by Vivado to obtain a frequency performance range.

Fig. 5. Effect of post-placement pipelining on clock frequency of the design. NSGA-II delivers 650 MHz without extra pipelining, while CMA-ES, Annealing, and Manual placement requires at least one stage. NSGA-II and CMA-ES achieve 750+ MHz with two stages, while SA requires four stages.

In Figure 5, we show the improvement in frequency as a function of number of pipeline stages inserted along the long wires by RapidLayout. We note that NSGA-II delivers 650 MHz frequency with no pipelining, while others requires at least one stage. Therefore, NSGA-II saves $\approx 6\%$ registers at pipelining as shown in Table I. NSGA-II wins over manual

design at every depth, and CMA-ES exhibits the most stable performance. Systolic array operation at 750+ MHz should be possible with a planned future design refinement of the array design. CMA-ES and NSGA-II can deliver this with only two pipeline stages, while SA requires four stages to achieve the same frequency.

D. Transfer Learning

TABLE II
TRANSFER LEARNING PERFORMANCE: VU3P, VU11P AS SEED DEVICES

Device	Design Size (conv units)	Impl.Runtime (mins.)	Frequency (MHz)	Placement Runtime	
				Scratch (s)	Transfer (s)
<i>xcvu3p</i>	123	46.4	718.9	428.3	-
<i>xcvu5p</i>	246	56.9	677.9	396.0	55.7 (7.1 \times)
<i>xcvu7p</i>	246	55.1	670.2	345.4	44.2 (7.8 \times)
<i>xcvu9p</i>	369	58.4	684.9	316.5	45.5 (7 \times)
<i>xcvu11p</i>	480	65.2	655.3	695.9	-
<i>xcvu13p</i>	640	69.4	653.2	704.9	58.8 (12 \times)

RapidLayout is capable of delivering high-quality placement results on devices with different sizes, resource ratio, or column arrangements with transfer learning ability. Transfer learning uses the genotype of an existing placement as a starting seed for initializing the placement search on a new device. We partition Xilinx UltraScale+ family into two groups with similar number of hard block columns. We choose VU3P and VU11P as “seed” devices on which RapidLayout generates placement from scratch with NSGA-II. Thereafter, placement results on seed devices are migrated to destination devices in the same group. In Table II, we compare placement runtimes with and without transfer learning across a range of FPGA device sizes. We observe that transfer learning accelerates the optimization process by 7–12 \times . If we observe the total implementation runtime column, we note that SLR replication ensures that the increase in overall runtime (46 mins. \rightarrow 69 mins., 1.5 \times) with device size is much less than the FPGA capacity increase (123 \rightarrow 640, 5.2 \times).

V. CONCLUSIONS

We present an end-to-end hard block placement workflow for resource intensive systolic array designs on modern heterogeneous FPGAs. We show how to outperform conventional simulated annealing and state-of-art analytical placement with evolutionary algorithms on metrics such as runtime, bounding box size, pipelining cost, and clock period. We formulate the placement of hard blocks as an optimization problem that targets the twin objectives of wirelength and maximum bounding box. RapidLayout delivers an automatic placement-and-routing workflow $\approx 5\text{--}6\times$ faster than Vivado that eschews manual placement effort. Evolutionary algorithms outperform VPR’s annealer, UTPlaceF analytical placer, manual placement by 33%– $\approx 30\times$ in runtime, 1.7–3.7 \times improvements in wirelength and 2–3 \times in bounding box sizes. These algorithms also save 6–16% register requirements to meet the 650 MHz operating frequency constraints. RapidLayout also employs transfer learning to quickly generate placements 7–12 \times faster for similar FPGA devices without requiring a full placement.

RapidLayout will be open-sourced to the community.
